(Received 20 July 2010; revised manuscript received 8 December 2010; published 31 January 2011)

The collisional magnetic reorientation rate constant g_R is measured for magnetically trapped atomic dysprosium (Dy), an atom with large magnetic dipole moments. Using buffer gas cooling with cold helium, large numbers ($>10^{11}$) of Dy are loaded into a magnetic trap and the buffer gas is subsequently removed. The decay of the trapped sample is governed by collisional reorientation of the atomic magnetic moments. We find $g_R = 1.9 \pm 0.5 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$ at 390 mK. We also measure the magnetic reorientation rate constant of holmium (Ho), another highly magnetic atom, and find $g_R = 5 \pm 2 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ at 690 mK. The Zeeman relaxation rates of these atoms are greater than expected for the magnetic dipole-dipole interaction, suggesting that another mechanism, such as an anisotropic electrostatic interaction, is responsible. Comparison with estimated elastic collision rates suggests that Dy is a poor candidate for evaporative cooling in a magnetic trap.

I. INTRODUCTION

The rare-earth-metal atoms dysprosium and holmium have some of the largest atomic magnetic dipole moments, with $\mu_{\text{Dy}} = 9.94 \mu_B$ and $\mu_{\text{Ho}} = 8.96 \mu_B$ [1]. Because the dipole-dipole interaction scales with the square of the dipole moment μ , there is much interest in creating ultracold degenerate gases of highly magnetic atoms. Strong magnetic dipole interactions yield an array of new effects in degenerate gases, including new phase transitions [2], modifications of the Bose-Einstein condensate (BEC) excitation spectrum [3], and trap-dependent BEC stability [4,5]. The study of magnetic dipole interactions in cold gases can also serve as a model for the behavior of the electric dipole interaction of trapped polar molecules, a new and increasingly promising area of ultracold degenerate systems. Further, the electronic spectrum of Dy offers opportunities for precision measurements [6–9], quantum computation [10], and a test of parity nonconservation [11].

The complex electronic structures of Dy and Ho that lead to the large magnetic moments also make them more difficult to trap and cool than closed-shell or S -state atoms, which are the most commonly studied degenerate gases. The isotropic electrostatic structure of closed-shell atoms ensures that spherically symmetric interactions dominate collision processes. For atoms whose outermost electronic shell has nonzero orbital angular momentum, or open-shell atoms, the electrostatic anisotropic interaction can play the determining role in trap loss and limit the efficiency of evaporative cooling. For instance, experiments with metastable Sr [12,13] and Yb [14] and theoretical studies with O [15] show that these atoms undergo magnetic moment reorientation in nearly every collision due to electron anisotropy. Consequently, collision processes in cold gases with anisotropic electrostatic interactions present a new challenge to theory and a new area of exploration for experiment [16]. Both Dy and Ho have a highly anisotropic unfilled $4f_{10}$ shell.

Recent experiments in trapping large numbers of Dy and Ho atoms using ^3He buffer gas cooling [17] have demonstrated that in collisions with He, Dy exhibits suppressed anisotropy,

leading to a large ($>10^5$) ratio of elastic to inelastic collisions and allowing efficient cooling with a He buffer gas. Theory suggests [18,19] that this suppression is due to the filled $5s$ and $6s$ shells which extend to a larger radius than the more tightly bound unfilled $4f$ shell. The interplay of the short-range anisotropic electrostatic interaction and the magnetic dipole-dipole interaction may offer novel ultracold collisional physics. The study of these interactions in the sub-Kelvin regime is important for cooling of a broader range of atoms to ultracold temperatures.

Using buffer gas cooling with ^3He , we have magnetically trapped large numbers ($>10^{11}$) of Dy atoms at temperatures around 400 mK and measured the rate of magnetic relaxation in collisions between two Dy atoms. After removing the buffer gas, we monitor the trap population by measuring the optical density using atomic absorption spectroscopy. From this evolution we measure the rate of trap decay due to inelastic two-body collisions and extrapolate the magnetic reorientation rate constant. We perform a similar measurement for trapped Ho atoms at 700 mK. We observe inelastic magnetic moment reorientation rates for both Ho and Dy that are at least an order of magnitude larger than expected due to the magnetic dipole-dipole interaction. Comparison of these rates to other buffer gas cooled atoms [20–22] suggest that anisotropic electrostatic interactions dominate the inelastic collision cross section for these open-shell atoms.

II. EXPERIMENTAL METHODS

The measurements were conducted in a buffer gas cooling apparatus. The essentials of the experimental apparatus are depicted in Fig. 1 and described in more detail elsewhere [23]. The apparatus consists of a G10 Garolite composite cell within the bore of a superconducting anti-Helmholtz magnet. The magnet forms a linear quadrupole trap with the trapping volume defined by the magnetic field at the cell walls, which can be as large as 4 T. Majorana trap losses are negligible in our experiment at the temperatures and trap depths used. The cell

FIG. 1. (Color online) Experimental cell.

is thermally anchored via a flexible copper heat link to the cold plate of a dilution refrigerator at 30 mK. A heater is used to control the cell temperature between 100 mK and 1 K. Copper wires running the length of the cell provide thermal contact between the cell top and bottom. The lower chamber of the cell forms the trapping chamber, into which ^3He is introduced via a fill line. The upper chamber holds a charcoal absorption pump. The two chambers are separated by a cryogenic, nonmagnetic valve that is opened in 40 ms via an external cable.

A probe laser of diameter 5 ± 1 mm is tuned to resonance with the trapped ground-state atoms. It passes through the center of the atom cloud via a sapphire window at the cell bottom. The laser is retroreflected from a mirror suspended at the top of the trapping chamber. The reflected light beam, which has passed through the trapped atoms twice, is compared to a reference beam, resulting in a measurement of atomic optical density. The probe beam power ($\sim 1 \mu\text{W}$) is far below the saturation of the transition and is shuttered unless the trap population is being measured in order to minimize its influence on trap lifetime. The probe laser is scanned across the Dy $^5I_8 \rightarrow ^5(8,1)_7$ transition at 404.71 nm. (The numbers in parentheses indicate the angular quantum numbers of the excited state in the J - J coupling scheme.) We interrogate the Ho $^4I_{15/2} \rightarrow ^4(15/2,1)_{17/2}$ transition at 410.5 nm [1]. Optical density of the atom cloud is measured at each point in the spectrum.

Initially, the trapping region is filled with ^3He atoms at a density of $\sim 10^{16} \text{ cm}^{-3}$ and a temperature chosen between 250 and 600 mK. With the trap on, Dy is ablated using a 10-ns pulse from a 532-nm Nd:YAG laser. The gas of hot atoms liberated by the ablation pulse is translationally thermalized to the buffer gas temperature after ~ 100 elastic collisions with the buffer gas. After waiting 200 ms for the atoms to diffuse into the center of the magnetic trap, the buffer gas is removed by opening the cryogenic valve, reducing the ^3He density to $< 10^{10} \text{ cm}^{-3}$ in ~ 100 ms. The majority of the atoms ($> 80\%$) remain trapped. At this point, the atom population is measured

as a function of time to determine the atomic inelastic collision rate.

III. RESULTS

We extract physical parameters of the atom cloud, such as atom number, temperature, and state distribution, by fitting the observed atomic optical density spectrum to a simulation [21,24] of the optical absorption of the trapped atoms. To accurately simulate the spectrum, we specify all the related spectroscopic parameters for the transition: the isotopic distribution and frequency shifts, Landé g factors, and ground- and excited-state quantum numbers and hyperfine constants. The parameters used are summarized in Table I. Most of these constants are found in the literature [1,27]. However, the Dy $^5(8,1)_7$ state isotope shifts and hyperfine constants could not be located. Instead, these constants were approximated by fitting the relative heights and locations of the common isotope peaks in Dy spectra taken at zero magnetic field; see Fig. 2.

At low He densities, the evolution of the number N_a of atoms in the $m_J = J$ stretched state can be described by [28]

$$\dot{N}_a = -g_b n_b N_a - (f_a g_a + g_R) N_a^2 / 8V, \quad (1)$$

where n_b is the residual density of ^3He in the cell, and $g_b n_b$ is the loss rate due to atom- ^3He collisions. g_a is the rate coefficient for elastic atom-atom collisions, and g_R is the rate coefficient for magnetic moment reorienting atom-atom collisions. V is the effective volume of the trap; the factor of $1/8$ in Eq. (1) arises from averaging the square of the local atom density over the linear quadrupole trap. f_a is the constant of proportionality between the rate of elastic atom-atom collisions and the rate of evaporation over the trap edge. For atoms at temperature T_a and trap depth U_{trap} , $f_a \sim e^{-U_{\text{trap}}/k_B T_a}$.

If the first term in Eq. (1) dominates, the trap population decays exponentially and is referred to as “one-body” loss; the rate is proportional to N_a . However, if the second term

FIG. 2. (Color online) Example of a Dy spectrum at zero magnetic field. There are five isotopes of Dy with occupation greater than 2%. From the spacings of the isotope peaks for ^{163}Dy and ^{161}Dy at zero field, we estimate the hyperfine constants (A , B) for the $^5(8,1)_7$ excited state (see Table I).

TABLE I. Spectroscopic parameters used in this work. For parameters not available in the literature, we estimated the values by fitting the isotope peak heights and locations in spectra taken at zero magnetic field.

dominates, the atom number decay obeys the “two-body” equation

$$N_a(t) = \frac{N_0}{N_0 g t / 8V + 1}, \quad (2)$$

with

$$g = f_a(U_{\text{trap}}, T_a)g_a + g_R. \quad (3)$$

For this measurement, we performed experiments at different values of U_{trap} but constant T_a in order to test the first term of Eq. (3). We found that g does not vary systematically as a function of U_{trap} , suggesting that f_a is small in our trap and losses due to evaporation over the trap edge are negligible. Therefore, in the following analysis we assume $g = g_R$.

Figure 3 shows a typical spectrum of Dy atoms in thermal equilibrium in a 1.9 T trap, 2 s after buffer gas removal. The spectral fit yields $N = 1.2 \times 10^{11}$ and $T = 390$ mK. This corresponds to a ratio of U_{trap} to $k_B T_a$ of 12.5 and an atom cloud approximately 6 mm in diameter, exploring an average field of 0.2 T. Atoms with $m_J \leq 3$ will not be trapped. Atoms with $m_J > 4$ remain weakly trapped and will contribute to the spectra. However, we observe a $J \rightarrow J - 1$ transition. Therefore, the Dy stretched state $m_J = 8$ population can only undergo $\Delta m_J = -1$ optical transitions. Trapped

FIG. 3. (Color online) Measured spectrum of Dy in a 1.9 T deep magnetic trap, 2 s after ablation. The line shows a fit to the spectrum, yielding $N = 1.2 \times 10^{11}$ and $T = 390$ mK. By comparing the optical density of the $\Delta m_J = -1$ peak to that of the $\Delta m_J = 0$ peak, we measure a stretched $m_J = 8$ population of 80%.

atoms in lower m_J levels contribute to the $\Delta m_J = 0$ transition signal. This allows us to estimate the fraction of Dy atoms in the stretched state by comparing the optical absorption in $\Delta m_J = -1$ transitions to that in $\Delta m_J = 0$ transitions. We find that after 2 s, more than 80% of the Dy are in the $m_J = 8$ state and the atoms remain similarly distributed for the lifetime of the trap. This suggests that a fast mechanism, such as spin exchange, is working to purify the population of the trap into the stretched state.

Spin exchange is forbidden in stretched state atom collisions [29]. Two-body decay of this population therefore results from inelastic processes which couple the magnetic moment to a nonspin angular degree of freedom (e.g., collisional or electronic angular momentum). Because our trapped population is mostly stretched state atoms, we assign the measured atom loss to inelastic magnetic moment reorienting collisions. Thermal excitations of atoms in nonstretched states may lead to a small underestimate (<10%) of the inelastic rate.

To confirm that the decay is due to a two-body process, we plot the inverse of the Dy atom number as a function of time in Fig. 4. In this plot, two-body decay appears as a straight line with slope $g_R/8$ while one-body decay would appear as a positive exponential. We fit to a one-body, two-body, and combined decay profiles. We find that a two-body fit with no one-body component results in the smallest reduced χ^2 . This confirms that the He buffer gas has been successfully removed and we are measuring losses due only to ground-state atom-atom interactions. We measure the rate of lifetime-limiting inelastic Dy-Dy collisions to be $g_R = 1.9 \pm 0.5 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$ at 390 ± 30 mK. This corresponds to an inelastic cross section of $1.9 \times 10^{-14} \text{ cm}^2$.

We also measured the rate of two-body trap loss of cold atomic holmium-holmium collisions in our apparatus; the evolution of the Ho trap population is also shown in Fig. 4. We derive the collision rate using the spectroscopic parameters in Table I and the same procedure as described for Dy. We find that the magnetic reorientation rate for Ho is $g_R = 5 \pm 2 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ at 690 ± 50 mK and an inelastic cross section of $1.2 \times 10^{-13} \text{ cm}^2$. We find the Ho decay is best fit by the two-body decay model, indicating successful removal of the buffer gas. However, the error on this measurement is larger than in the Dy experiment due to smaller numbers

FIG. 4. (Color online) Reciprocal of atom number density evolution of trapped Dy and Ho atoms. Each point is the result of fitting temperature and atom number of the atomic spectrum at each time (e.g., Fig. 3). Temperature is 390 ± 30 mK and 690 ± 50 mK for Dy and Ho, respectively, for the lifetime of the trap. Plotted as V/N_a vs time, linear two-body decay is easily distinguished from exponential one-body decay. g_R is derived from the slope of the two-body fit.

of trapped atoms and the overlap of spectral features of the hyperfine states. Uncertainty of the state distribution makes it difficult to quantify the effect of thermal excitations on this system; the actual Ho-Ho inelastic collision rate could be twice as large as the loss rate we measure [30].

IV. DISCUSSION

Elastic collisions. In order to achieve efficient evaporative cooling, it is necessary to have multiple elastic collisions for every inelastic collision that leads to trap loss. A reasonable estimate for the Dy-Dy elastic collision cross section at sub-Kelvin temperatures can be obtained by taking half of the unitarity limit [31]:

$$\sigma_{\text{el}} \approx \frac{\hbar^2 \pi}{mE} \sum_{\ell} (2\ell + 1). \quad (4)$$

At 390 mK, we can expect multiple partial waves (ℓ up to 30) to contribute to elastic scattering and $\sigma_{\text{el}} \approx 4.5 \times 10^{-13}$ cm², with larger values possible if shape resonances are present. This estimate implies that Dy should undergo only 20 thermalizing elastic collisions for every inelastic loss, making evaporative cooling rather inefficient. This conclusion is supported by the prohibitively large loss of trapped atoms observed when we attempt to evaporatively cool the sample.

Inelastic collisions. Different physical mechanisms are responsible for two-body inelastic collision processes between magnetically trapped atoms in the stretched state; the magnetic dipole interaction and electrostatic interactions of the valence shells may be expected to play a significant role in this system. The following discussion will show that the magnetic dipole interaction, though very strong between highly magnetic atoms, does not explain the rapid collisional reorientation rate we measure.

The magnetic dipole interaction has been well studied in alkali-metal gases. The Hamiltonian for a collision of two dipolar atoms can be written as

$$H(\vec{r}) = \frac{\mu_0 \mu_B^2 g_J^2}{4\pi r^3} [\vec{J}_1 \cdot \vec{J}_2 - 3(\vec{J}_1 \cdot \hat{r})(\vec{J}_2 \cdot \hat{r})] + V(\vec{r}), \quad (5)$$

where μ_0 is the magnetic constant, \vec{r} is the vector of internuclear separation, and all other interatomic interactions are included in $V(\vec{r})$.

Using the Born approximation, the dipolar relaxation rate of spin-polarized atoms due to dipolar interactions can be shown to scale according to [32]

$$g_{\text{dip}} \propto J^3 g_J^4, \quad (6)$$

where J is the total angular momentum quantum number, and g_J is the Landé g factor. While the actual cross section depends on the exact form of $V(\vec{r})$, an estimate of the dipolar relaxation rate is made by scaling measurements from other atomic systems using Eq. (6). We estimate the expected Dy relaxation rates from measurements of inelastic rates for atoms whose reorientation is dominated by magnetic dipolar relaxation. Using data from trapped Cr at 200 mK [20] and Eu at 160 mK [21] we compare our measured rate constant of $g_R = 1.9 \pm 0.5 \times 10^{-11}$ cm³ s⁻¹ to the expected $g_{\text{Dy}} = 3.2 \times 10^{-13}$ and 1.1×10^{-12} cm³ s⁻¹ scaled for temperature and magnetic moment from Eu and Cr, respectively. Our measured Zeeman relaxation rate is one to two orders of magnitude larger than these estimated magnetic dipolar relaxation rates, suggesting that dipolar relaxation is not solely responsible for this fast decay.

We also find that the rates for Ho and Dy are significantly smaller than rates in similarly trapped Er and Tm, 3.0×10^{-10} and 1.1×10^{-10} cm³ s⁻¹, respectively [22], which have smaller magnetic dipoles. This observation further suggests that magnetic dipole-dipole interactions are not the dominant mechanism for Zeeman relaxation in collisions between rare-earth-metal atoms. The interaction of anisotropic electrostatic potentials could be responsible for the large rate of Zeeman relaxation and short trap lifetime. However, theory is needed to confirm this.

Recently, a magneto-optical trap of 5×10^8 Dy atoms at temperatures around 500 μ K was reported in the literature [33]. The inelastic two-body loss rate of ¹⁶⁴Dy was measured to be 2.1×10^{-10} cm³ s⁻¹. Comparison with our measurement at higher temperatures suggests a temperature dependence of the total inelastic scattering cross section as $E \rightarrow 0$ [34]. Further experiments will be necessary to fully understand these collisional processes in complex atoms.

V. CONCLUSION

Our determination of the inelastic cross section and estimate of the elastic cross section indicates that evaporative cooling of Dy in a magnetic trap will be very inefficient. Despite this limitation, we were able to adiabatically cool $>10^9$ Dy atoms to 50 mK in our buffer gas apparatus by rapidly changing the magnetic gradient. If cooling to a few mK can be accomplished, it may be possible to load a far off-resonant dipole trap (FORT) [35] using additional laser cooling. However, care must be taken to deal with scattering into dark states. A 5 mK deep dipole trap for Dy could be

constructed using 200 mW of 420-nm light (available from a doubled Ti:Al₂O₃ laser), detuned two THz from the $\Delta J = 1$ transition and focused to a 30- μm waist, having an absorption rate of 400 s⁻¹. Once in an optical trap, efficient cooling could be achieved using evaporative or demagnetization cooling [36]. The large calculated inelastic cross section for Ho would make evaporative cooling of magnetically trapped Ho even more difficult; we were unable to achieve any adiabatic cooling of this atom.

Dy and Ho are promising atoms for studying the effects and role of large magnetic dipole interactions. However,

we find that the large inelastic collision rate, possibly due to anisotropic electrostatic interactions, is prohibitive to using evaporative cooling techniques on magnetically trapped atoms in the low-field-seeking state. Other trapping and cooling schemes will be necessary to reach the degenerate regime.
